Abstract

Traffic control measures like variable speed limits or outflow control can be used to influence the route choice of drivers. In this paper we develop a day-to-day route choice control method that is based on model predictive control (MPC). A basic route choice model forms the basis for the controller. We show that for the given model and for a linear cost function it is possible to reformulate the MPC optimisation problem as a mixed integer linear programming (MILP) problem. For MILP problems efficient branch-and-bound solvers are available that guarantee to find the global optimum. This global optimisation feature is not present in most of the other mixed integer optimisation methods that are usually used for MPC (such as simulated annealing, genetic programming, tabu search, etc.). We also illustrate the efficiency of the proposed approach for a simple simulation example involving speed limit control.

Keywords

Traffic management, route choice, model-based predictive control, optimisation
1 Introduction

Route choice takes place when there exist two or more routes between an origin and a destination. In this case, drivers select a route based on their preferences. The choices of the drivers lead to a traffic assignment, which describes how the vehicles are divided over the network. When drivers select their route solely based on their own preferences, this traffic assignment may lead to large traffic flows on narrow or dangerous roads, to socially undesired situations (e.g., too many vehicles in residential areas or near primary schools), or to too large flows near urban areas or nature reserves causing pollution and noise. Road administrators can try to prevent these unwanted situations by influencing the route choice of the drivers. In Haj-Salem & Papageorgiou (1995); Taale & van Zuylen (2003) it has been shown that traffic control measures that do not directly influence route choice but that do have an impact on the travel time (such as traffic signals, variable speed limits, and ramp metering) can be used for this purpose.

Traffic control methods that incorporate the effect of control measures on route choice are described in, e.g., Bellemans et al. (2003); Karimi et al. (2004); Wang & Papageorgiou (2002). In this paper we consider control methods that can be used for steering the traffic flows in a network to a desired traffic assignment. This will result in settings for the outflow capacity of the links, or for the speed limits on these links.

We use model predictive control (MPC) (Camacho & Bordons, 1995; Maciejowski, 2002) as control method. As prediction model we use the static route choice model we have presented in van den Berg et al. (2008). This model is based on the assumption that the experienced travel time is the most important factor in route choice, which is also argued for in Bogers et al. (2005). Moreover, the model allows for an analytic description of the behaviour of traffic flows in a network. MPC uses this route choice model combined with an optimisation algorithm to determine the optimal settings for the traffic control measures. MPC has already been applied previously for traffic control in, e.g., Hegyi (2004); Bellemans (2003); Kotsialos et al. (2002), where it resulted in non-linear nonconvex continuous or mixed integer optimisation problems. In our specific case the whole control problem can be formulated as a mixed integer linear programming (MILP) problem, for which fast solvers are available, which reduces the required computation time. Furthermore, the MILP approach also results in a globally optimal solution.

This paper is organised as follows. We first describe the route choice model and the MPC-based approach for route choice control in Section 2. In Section 3 we reformulate the problem as an MILP problem. Next, the proposed control approach is applied to a simulation example in Section 4. Section 5 concludes the paper.

2 Route choice control

In this section we briefly recapitulate the day-to-day route choice model and the corresponding MPC-based route choice control approach that we have developed in van den Berg et al. (2008).

2.1 Route choice model

To illustrate our approach we will use the simple two-route network given in Figure 1 throughout the paper. This network consists of one origin and one destination that are connected via two routes.

\begin{figure}[h]
\centering
\includegraphics[width=0.4\textwidth]{network.png}
\caption{Network with two routes}
\end{figure}

Network variables

Consider the network of Figure 1. Each route \( r \) (\( r \in \{1, 2\} \)) can be described by the following parameters, where \( d \) is the counter for the days. The length of route \( r \) is denoted by \( l_r \) (km), and its capacity is denoted by \( C_r \) (veh/h). The speed limit \( v_r(d) \) (km/h) gives the maximum speed that is allowed on route \( r \) at day \( d \). This speed limit will be bounded between a minimum speed limit \( v_{r_{\text{min}}}(d) \) (km/h) and a maximum speed limit \( v_{r_{\text{max}}}(d) \) (km/h). The outflow limit \( Q_r(d) \) (veh/h) gives the number of vehicles per hour that are allowed to leave the route. The maximum value of the outflow limit, \( Q_{r_{\text{max}}}(d) \) (veh/h), is equal to or lower than the actual capacity of the road: \( Q_{r_{\text{max}}}(d) \leq C_r \). The minimum value \( Q_{r_{\text{min}}}(d) \) (veh/h) can be selected to prevent almost total closure of the road when outflow control is applied.

We consider one part of the day, e.g., the morning peak. We denote this period by the time interval \([0, T]\) and we assume that the demand \( Q_{\text{in}}(d) \) (veh/h) in the network is constant during \([0, T]\). The demand is distributed over the two routes according to the turning rate \( \beta(d) \), which gives the percentage of the vehicles that select route 1.

An important characteristic of the routes is the “free-flow” travel time, which describes the time that a vehicle needs to travel a route when there is no delay due to congestion. The free-flow travel time at day \( d \) along route \( r \) is given by:

\[
\tau_r^{\text{free}}(d) = \frac{l_r}{v_r(d)}.
\]

Travel time model

The model of van den Berg et al. (2008) for the mean experienced travel time assumes that the travel time \( \tau_r \) on a route has two components: the time spent in the queue \( \tau_r^{\text{queue}} \) and the free-flow travel time \( \tau_r^{\text{free}} \):

\[
\tau_r(d) = \tau_r^{\text{queue}}(d) + \tau_r^{\text{free}}(d).
\]

The time in the queue \( \tau_r^{\text{queue}} \) depends on the number of vehicles in the queue. We assume that the queues are vertical queues that build up at the end of each route. So during the period \([0, T]\) the queue grows as shown in Figure 2.
Since the number of vehicles leaving the queue per time unit is at most $Q_1$, the mean time that the vehicles spend in the queue at the end of route 1 is given by:

$$
\tau_{1}^{\text{queue}}(d) = \begin{cases} 
\frac{N_1^{\text{mean}}(d)}{Q_1(d)} = \frac{(\beta(d)Q_{\text{in}}(d) - Q_1(d))(T - \tau_{1}^{\text{free}}(d))}{2Q_1(d)} & \text{if } \beta(d)Q_{\text{in}}(d) > Q_1(d) \\
0 & \text{if } \beta(d)Q_{\text{in}}(d) \leq Q_1(d) 
\end{cases},
$$

where $N_1^{\text{mean}}(d)$ is the average number of vehicles in the queue at the end of route 1. These formulas can be rewritten more compactly as

$$
\tau_{1}^{\text{queue}}(d) = \max \left( 0, \frac{(\beta(d)Q_{\text{in}}(d) - Q_1(d))(T - \tau_{1}^{\text{free}}(d))}{2Q_1(d)} \right),
$$

and thus

$$
\tau_1(d) = \max \left( 0, \frac{(\beta(d)Q_{\text{in}}(d) - Q_1(d))(T - \tau_{1}^{\text{free}}(d))}{2Q_1(d)} \right) + \tau_{1}^{\text{free}}(d). \quad (2)
$$

A similar reasoning for route 2 results in

$$
\tau_2(d) = \max \left( 0, \frac{(1 - \beta(d))Q_{\text{in}}(d) - Q_2(d))(T - \tau_{2}^{\text{free}}(d))}{2Q_2(d)} \right) + \tau_{2}^{\text{free}}(d). \quad (3)
$$

**Route choice model**

Route choice models describe the route choice of drivers at locations where a route must be selected. The model of van den Berg et al. (2008) updates the turning rates for the
next day \( d + 1 \) based on the difference in travel times on the current day \( d \) between the two routes, while also taking into account that the turning rates are bounded between 0 and 1. This yields

\[
\beta(d + 1) = \min \left( 1, \max(0, \beta(d) + \kappa(\tau_2(d) - \tau_1(d))) \right).
\]  

(4)

Here \( \kappa \) includes the fraction of drivers that change their route from one day to the next based on the travel time difference.

\[ \]

2.2 Route choice control using MPC

Outflow control and speed limit control

Now two control inputs can be selected for influencing the route choice of the drivers with existing control methods: outflow limits and speed limits. Both inputs influence the travel time of the drivers, and thus indirectly the route choice. Outflow control limits the flow that can leave a link. The outflow can be lowered using, e.g., traffic signals and ramp metering installations. The control via the speed limits influences the free-flow travel time on the two routes. Variable message signs could be used to display the speed limits.

MPC: Principle of operation

Just as in van den Berg et al. (2008) we will use Model Predictive Control (MPC) (Maciejowski, 2002) to determine the optimal values for the outflow control limits and speed control limits. Below we will briefly present this method.

In MPC for route choice control the goal is to determine the control inputs \( c \) that optimise a cost function \( J \) over a given prediction period of \( N_p \) days ahead, given the current state of the network, the future demand, and a model of the system, and subject to operational and other constraints. This results in a sequence of optimal control inputs \( c^*(d), c^*(d + 1), \ldots, c^*(d + N_p - 1) \). To reduce the computational complexity often a control horizon \( N_c \) (\( N_c < N_p \)) is introduced and the control sequence is constrained to vary only for the first \( N_c \) days, after which the control inputs are set to stay constant (i.e., \( c(d + j) = c(d + N_c - 1) \) for \( j = N_c, \ldots, N_p - 1 \)).

MPC uses a receding horizon approach, i.e., of the optimal control signal sequence only the first sample \( c^*(d) \) is applied to the system. Next, at day \( d + 1 \), the procedure is repeated given the new state of the system, and a new optimisation is performed for days \( d + 1 \) up to \( d + N_p \). Of the resulting control signal again only the first sample is applied, and so on. This is called the receding horizon approach.

MPC for route choice control

In the context of route choice control typical examples of cost functions are the total time the vehicles spend in the network, the total queue length, or the norm of the difference between the realised flows and the desired flows on the routes. These cost functions serve either to handle as much traffic as possible in a short time, or to keep vehicles away from protected routes (e.g., routes through residential areas or nature reserves).
The state of the system is in our case given by the mean travel times, and the mean turning rates for the day. As (prediction) model we could use the route choice model of Section 2. The control inputs are the outflow limits and/or the speed limits. Typical constraints are maximum and minimum values for these limits as well as maximal travel times or maximal waiting times in the queues.

In van den Berg et al. (2008) the control signal was assumed to be real-valued. This results in continuous nonlinear nonconvex optimisation problems that could be solved using multi-start local search methods (like SQP, pattern search, etc.) or (semi-)global optimisation methods like genetic algorithms or simulated annealing (Pardalos & Resende, 2002). Note that these approaches in principle only yield a suboptimal solution as in practice it is not tractable to find the global optimum of the continuous nonlinear nonconvex optimisation problems that arise in MPC for route choice control.

In the remainder of this paper we will only allow discrete values for the control input (in particular for the speed limits). In the next section we will show that for linear cost functions this will then result in a mixed integer linear programming (MILP) problem, for which efficient solvers exist that guarantee to find the global optimum. Note that in principle a brute-force enumeration approach could also be used, but in practice such an approach is not tractable, especially in case there is a large number of discrete speed limit values and/or a large number of routes with speed limit control.

3 MPC for route choice control using mixed integer programming

In this section we show that for linear cost functions the MPC route choice optimisation problem can be recast as an MILP problem. In particular, we will consider the case of speed control with no outflow control. For outflow control without speed limit control and for combined speed and outflow control a similar reasoning will also result in an MILP problem.

3.1 Rules for creating mixed integer linear inequalities

To formulate the route choice control problem described above as an MILP problem, we first have to remove the nonlinearities from the model. This is done by recasting the nonlinear equations into linear ones, and by introducing additional auxiliary variables. To perform these transformations we use the following equivalences (Bemporad & Morari, 1999), where \( \delta \) represents a binary valued scalar variable, \( y \) a real valued scalar variable, and \( f \) a function defined on a bounded set \( X \) with upper and lower bounds \( M \) and \( m \) for the function values:

\[
P1: [f(x) \leq 0] \leftrightarrow [\delta = 1]
\]

is true if and only if

\[
\begin{align*}
  f(x) &\leq M(1-\delta) \\
  f(x) &\geq \varepsilon + (m-\varepsilon)\delta,
\end{align*}
\]

where \( \varepsilon \) is a small positive number\(^1\) (typically the machine precision),

\(^1\)We need this construction to transform a constraint of the form \( y > 0 \) into \( y \geq \varepsilon \), as in MILP problems only nonstrict inequalities are allowed.
P2: $y = \delta f(x)$ is equivalent to

$$
\begin{align*}
y &\leq M \delta \\
y &\geq m \delta \\
y &\leq f(x) - m(1 - \delta) \\
y &\geq f(x) - M(1 - \delta).
\end{align*}
$$

3.2 Model equations

For simplicity we assume that the speed limits can only have two values $v_a$ and $v_b$ (note however that an extension to more than two values is straightforward). The free-flow travel times corresponding to these values can be represented by one binary variable $\delta$ as follows. Define (cf. (1))

$$
\tau_{r,a} = \frac{l_r}{v_a}, \quad \tau_{r,b} = \frac{l_r}{v_b}, \quad \text{and} \quad \Delta_r = \tau_{r,b} - \tau_{r,a}.
$$

Then we can select $v_a$ or $v_b$ on route $r$ for day $d$ by introducing a binary variable $\delta_r(d)$ and setting

$$
\tau_{r,a}^\text{free} = \frac{l_r}{v_a} + \Delta_r \delta_r(d).
$$

Recall that we consider the case of speed control with no outflow control; so $Q_1(d) = C_1$ and $Q_2(d) = C_2$ for all $d$. If we substitute the above expression for $\tau_{r,a}^\text{free}$ in (2) we get

$$
\tau_1(d) = \max(0, y_3(d)) + \tau_{1,a}^\text{free} + \Delta_1 \delta_1(d) \quad (5)
$$

with

$$
y_3(d) = a_1 \beta(d) + a_2 \delta_1(d) \beta(d) + a_3 \delta_1(d) + a_4 \quad (6)
$$

with $a_1 = \frac{1}{2x_1} Q_\text{in}(d)(T - \tau_{1,a}^\text{free})$, $a_2 = -\frac{1}{2x_1} Q_\text{in}(d) \Delta_1$, $a_3 = \frac{1}{2} \Delta_1$, and $a_4 = -\frac{1}{2} (T - \tau_{1,a}^\text{free})$. By introducing an extra variable $y_1(d) = \delta_1(d) \beta(d)$ and using Property P2 with $f(x) = \beta(d)$, $m = 0$, and $M = 1$, (6) can be transformed into a system of linear inequalities. In a similar way $\tau_2(d)$ can be expressed as

$$
\tau_2(d) = \max(0, y_4(d)) + \tau_{2,a}^\text{free} + \Delta_2 \delta_2(d) \quad (7)
$$

with $y_4(d)$ given by

$$
y_4(d) = a_5 \beta(d) + a_6 y_2(d) + a_7 \delta_2(d) + a_8 \quad (8)
$$

with $a_5 = -\frac{1}{2x_2} Q_\text{in}(d)(T - \tau_{2,a}^\text{free})$, $a_6 = \frac{1}{2x_2} Q_\text{in}(d) \Delta_2$, $a_7 = -\frac{1}{2} \Delta_2 (Q_\text{in}(d) - C_2)$, and $a_8 = \frac{1}{2x_2} (Q_\text{in}(d) - C_2)(T - \tau_{2,a}^\text{free})$, and with $y_2(d) = \delta_2(d) \beta(d)$. Using Property P2 these equations can also be transformed into a system of linear inequalities.

Now define the auxiliary variables $\eta(d)$ and $\gamma(d)$ such that (cf. (4))

$$
\gamma(d) = \beta(d) + \kappa(\tau_2(d) - \tau_1(d)) \quad (8)
$$

$$
\eta(d) = \max(0, \gamma(d)) \quad (9)
$$
Then we have

$$\beta(d + 1) = \min(\eta(d), 1) \ .$$

(10)

Let us now discuss how these equations can be recast as a system of mixed integer linear inequalities.

Combining (5), (7), and (8) we get

$$\gamma(d) = \beta(d) - \kappa \max(0, y_3(d)) + \kappa \max(0, y_4(d))$$

$$- \kappa \Delta_1 \delta_1(d) + \kappa \Delta_2 \delta_2(d) + \kappa (\tau_{2,a}^{\text{free}} - \tau_{1,a}^{\text{free}}) \ .$$

Now we define binary variables $\delta_5(d)$ and $\delta_6(d)$ such that $\delta_5(d) = 1$ if and only if $y_3(d) \geq 0$, and $\delta_4(d) = 1$ if and only if $y_4(d) \geq 0$. Using Property P1 these equivalences can be recast as a system of linear inequalities. Now we have $\max(0, y_3(d)) = \delta_5(d)y_3(d)$ and $\max(0, y_4(d)) = \delta_4(d)y_4(d)$. So after introducing $y_5(d) = \delta_5(d)y_3(d)$ and $y_6(d) = \delta_6(d)y_4(d)$ and noting that both these expressions can be recast as a system of linear inequalities via Property P2, we get

$$\gamma(d) = \beta(d) - \kappa y_5(d) + \kappa y_6(d) + b_1 \delta_1(d) + b_2 \delta_2(d) + b_3$$

(11)

with $b_1 = -\kappa \Delta_1$, $b_2 = \kappa \Delta_2$, and $b_3 = \kappa (\tau_{2,a}^{\text{free}} - \tau_{1,a}^{\text{free}})$. Note that equation (11) is linear.

Now consider (9). If we define the binary variable $\delta_5(d)$ such that $\delta_5(d) = 1$ if and only if $y_5(d) \geq 0$ (note that this equivalence can be recast as a system of linear inequalities via Property P2), we get $\eta(d) = \delta_5(d)\gamma(d)$, which can in its turn also be expressed as a system of linear inequalities using Property P2.

Consider (10) and define the binary variable $\delta_6(d)$ such that

$$\delta_6(d) = 1 \text{ if and only if } \eta(d) \leq 1 \ .$$

Note that this equivalence can be recast as a system of linear inequalities via Property P2. It is easy to verify that now we have

$$\beta(d + 1) = \min(\eta(d), 1) = \delta_6(d)\eta(d) + 1 - \delta_6(d) \ ,$$

which after introducing the auxiliary variable $z(d) = \delta_6(d)\eta(d)$ (this equivalence can also be recast as a system of linear inequalities via Property P1), results in the linear equation

$$\beta(d + 1) = z(d) + 1 - \delta_6(d) \ .$$

If we now collect all variables for day $d$ in one vector

$$w(d) = [\beta(d) \ \delta_1(d) \ldots \delta_6(d) \ y_1(d) \ldots y_6(d) \ \gamma(d) \ \eta(d) \ z(d)]^T \ ,$$

we can express $\beta(d + 1)$ as an affine function of $w(d)$: $\beta(d + 1) = aw(d) + b$ for a properly defined vector $a$ and scalar $b$, where $w(d)$ satisfies a system of linear equations $Cw(d) = e$, $Fw(d) \leq g$, which corresponds to the various linear equations and constraints introduced above.
3.3 Cost function

To be able to transform the route choice control problem into an MILP problem, the cost function should be linear or piecewise affine. Possible goals of the controller that allow for such cost functions are reaching a desired flow on one of the routes, or minimising the flow on a route (with as constraint, e.g., a maximum allowed travel time on the other route — see also Section 3.4). The MPC cost function for a minimum flow on route 1 is given by:

$$J(d) = \min \sum_{j=1}^{N_p} \beta(d + j) Q_{in}(d + j)$$

Let us define

$$\bar{F}(d) = \left[ \begin{array}{c} \beta(d + 1) Q_{in}(d + 1) \\ \vdots \\ \beta(d + N_p) Q_{in}(d + N_p) \end{array} \right], \quad \bar{F}^{desired}(d) = \left[ \begin{array}{c} q^{desired}_1(d + 1) \\ \vdots \\ q^{desired}_1(d + N_p) \end{array} \right],$$

where $q^{desired}_1(d + j)$ denotes the desired flow on route 1 at day $d + j$. The MPC cost function corresponding to reaching a desired flow on route 1 is then given by:

$$J(d) = \min \|\bar{F}^{desired}(d) - \bar{F}(d)\|$$

using either the 1-norm or the $\infty$-norm. When a 1-norm is used, the problem can transformed into a linear one as follows:

$$\min \|\bar{F}^{desired}(d) - \bar{F}(d)\|_1 = \min \sum_{j=1}^{N_p} |q^{desired}_1(d + j) - \beta(d + j) Q_{in}(d + j)|$$

$$= \min \sum_{j=1}^{N_p} q(d + j)$$

s.t. $q(d + j) \geq q^{desired}_1(d + j) - \beta(d + j) Q_{in}(d + j)$

$q(d + j) \geq -q^{desired}_1(d + j) + \beta(d + j) Q_{in}(d + j)$

for $j = 1, \ldots, N_p$.

It is easy to verify that for the optimal solution of the latter problem we have

$$q^*(d + j) = \max (q^{desired}_1(d + j) - \beta^*(d + j) Q_{in}(d + j),$$

$$-q^{desired}_1(d + j) + \beta^*(d + j) Q_{in}(d + j))$$

$$= |q^{desired}_1(d + j) - \beta^*(d + j) Q_{in}(d + j)|$$

for all $j$.

Similarly, for the $\infty$-norm we have

$$\min \|\bar{F}^{desired}(d) - \bar{F}(d)\|_\infty = \min \max_{j=1, \ldots, N_p} |q^{desired}_1(d + j) - \beta(d + j) Q_{in}(d + j)|$$

$$= \min q$$

s.t. $q \geq q^{desired}_1(d + j) - \beta(d + j) Q_{in}(d + j)$

$q \geq -q^{desired}_1(d + j) + \beta(d + j) Q_{in}(d + j)$

for $j = 1, \ldots, N_p$,

which is also a linear programming problem.
3.4 Constraints

It might be useful to add a constraint on the travel time on the second route, because minimising, e.g., the flow on route 1 results in a higher flow and thus a longer travel time on route 2:

\[ \tau_2(d + j) \leq \tau_{2,\text{max}}(d + j) \quad \text{for } j = 0, \ldots, N_p - 1, \]

where \( \tau_{2,\text{max}}(d + j) \) denotes the maximal travel time on route 2 on day \( d + j \). Note that \( \tau_2(d + j) \) will not be a variable in the optimisation problem. However, using (7) we can easily eliminate it from the constraint (12). This yields the equivalent system of constraints

\[
\begin{align*}
\tau_{2,\text{free}} + \Delta_2 \delta_2(d + j) & \leq \tau_{2,\text{max}}(d + j) \\
y_4(d + j) + \tau_{2,\text{free}} + \Delta_2 \delta_2(d + j) & \leq \tau_{2,\text{max}}(d + j)
\end{align*}
\]

for \( j = 0, \ldots, N_p - 1 \). Note that these constraints are also linear.

An alternative constraint is to have a minimal or maximal flow on a given route. For route 2 this would result in

\[ F_2^{\text{min}}(d + j) \leq (1 - \beta(d + j)) Q_{\text{in}}(d + j) \leq F_2^{\text{max}}(d + j), \]

for \( j = 1, \ldots, N_p \), where \( F_2^{\text{min}}(d + j) \) and \( F_2^{\text{max}}(d + j) \) denote respectively the minimal and maximal allowed flow on route 2 on day \( d + j \). This constraint is also linear.

3.5 Overall mixed integer linear programming problem

If we collect the linear objective function and all the linear constraints introduced above into one big problem, we get an MILP problem in the variables \( w(d), w(d + 1), \ldots, w(d + N_p - 1), \beta(d + N_p) \) and \( q(d + 1), q(d + 2), \ldots, q(d + N_p) \) (when the 1-norm is used) or \( q \) (when the \( \infty \)-norm is used).

Although MILP problems are in general NP-hard, recently several efficient branch-and-bound MILP solvers (Fletcher & Leyffer, 1998) have become available. Moreover, there exist several commercial and free solvers for MILP problems such as, e.g., CPLEX, Xpress-MP, GLPK, or lp_solve (see Atamtürk & Savelsbergh (2005); Linderoth & Ralphs (2005) for an overview). In principle, — i.e., when the algorithm is not terminated prematurely due to time or memory limitations, — these algorithms guarantee to find the global optimum. This global optimisation feature is not present in most of the other mixed integer optimisation methods that are usually used for MPC (such as simulated annealing, genetic programming, tabu search, etc.).

4 Simulation example

In this section we illustrate the possibilities of the MPC-based route choice control method with a simulation example. As network we have selected the simple network given in Figure 1 and we apply speed limit control.

The parameters are selected as follows: \( \kappa = 0.25, C_1 = C_2 = 2000, l_1 = 4, l_2 = 6, v_a = 40, v_b = 100, \) and \( T = 1 \). This means that both routes have the same capacity, but

that route 1 has a lower free-flow travel time because it is shorter. The total demand is $Q_{\text{in}}(d) = 3000$ veh/h for all days. The initial turning rate $\beta(0)$ is 0.4.

As cost function we have taken the 1-norm, as described in Section 3.3. We have simulated a period of 20 days, where the prediction and control horizons of the MPC-based controllers are set to 8 days. For the sake of simplicity and to eliminate possible influences of model mismatches, we have used the same model for the simulation and for the prediction by the MPC controller. We have set the desired flow on route 1 to 1000 veh/h, which can, e.g., be useful when the route crosses a residential area. This lower desired flow on route 1 can lead to a large flow on route 2, which will result in congestion on this route. To prevent this congestion, we have put a limit of 2000 veh/h on the flow on route 2.

First, we have used the MILP formulation within the controller. The results are shown in Figure 3. The top plot shows the flow on route 1, which starts at 1200 veh/h, and then decreases until it starts oscillating around 1020 veh/h. These oscillations are caused by the interplay between the bound of 2000 veh/h on the flow on route 2 (see Figure 3 (middle)), and the repeated switching between the maximum and minimum values of the speed limit on route 1 (see Figure 3 (bottom)).

Recall that we have introduced the MILP formulation because it allows for finding the global optimum, and because it is fast. To illustrate these properties we compare the MILP formulation with three other optimisation methods: a multi-run genetic algorithm (Davis, 1991), multi-start simulated annealing (Eglese, 1990), and brute-force enumeration. As MILP solver we have used CPLEX, implemented through the cplex interface function of the Matlab Tomlab toolbox (Tomlab). For the genetic algorithm and simulated annealing method we have used the ga and simulannealbnd functions of the Matlab Genetic Algorithm and Direct Search Toolbox (The MathWorks, 2007) respectively. For all these optimisation functions we have specified that the values of the optimisation variables should be integers. For cplex the default settings were used; for ga and simulannealbnd we have implemented the constraint of the flow on route 2 through a penalty term and tuned the settings to get a near-optimal solution in
Figure 3: Flows and speeds limits with an MILP-based MPC controller
the shortest possible time. The resulting costs $J$ and the required computation times (on a 3 GHz Intel Pentium 4 processor) for the complete closed-loop simulation are given in Table 1. Clearly, the MILP approach outperforms the other approaches.

Next, we have re-run the genetic algorithm and the simulated annealing approach giving each of them a maximal CPU time of 2.23 s (i.e., the CPU time required by the MILP algorithm). The results of this experiment are given in Table 2. These results once again show that the MILP approach outperforms the other approaches.

5 Conclusions

We have considered a method based on model predictive control (MPC) to steer day-to-day route choice in traffic networks towards an optimal situation using existing traffic control measures like outflow control and variable speed limits. In general, this results in nonlinear nonconvex optimisation problems. However, we have shown that for a linear cost function the MPC optimisation problem can be recast as a mixed integer linear programming problem, for which efficient solvers exist that guaranteedly converge to a global optimum.

The proposed approach has been illustrated by means of a simulation example with speed limit control where the goal of the controller was to obtain a desired flow on one of the routes. The developed MILP algorithm has been compared with some other available optimisation approaches. For the case study the MILP algorithm has shown to be the fastest, and in addition it always returns the globally optimal solution.

Some topics for future are: extending the proposed approach to more complex networks with multiple origins, destinations, route choice locations, and routes, as well as including additional traffic control measures and demand profiles that vary during the period under consideration.
