Abstract

We consider a traffic light controlled intersection. First we construct a model that describes the evolution of the queue lengths (as continuous variables) in each lane. Next, we discuss how optimal and suboptimal traffic light switching schemes (with possibly variable cycle lengths) for this system can be determined. We also show that for a special class of objective functions suboptimal traffic light switching schemes can be computed very efficiently.

1 Introduction

As the number of vehicles and the need for transportation grow, cities around the world face serious road traffic congestion problems. On the short term the most effective measures in the battle against traffic congestion seem to be a selective construction of new roads and a better control of traffic through traffic management. Traffic light control can be used to augment the flow of traffic in urban environments by providing a smooth circulation of the traffic or by using "green waves", or to regulate the access to highways or main roads (ramp metering).

In this paper we study the optimal traffic light control problem for an intersection of two two-way streets\(^1\). We derive an approximate model that describes the evolution of the queue lengths as a continuous function of time. Starting from this model we can then compute the traffic light switching scheme that minimizes a criterion such as average queue length, worst case queue length, average waiting time, ..., thereby augmenting the flow of traffic and diminishing the effects of traffic congestion. We show that for a special class of objective functions an optimal traffic light switching scheme can be computed very efficiently. The main difference of the approach presented in this paper and most other existing methods is that we allow the green-amber-red cycle time to vary from one cycle to another. Furthermore, we use an optimization over a fixed number of switch-overs instead of an optimization over a fixed number of time steps.

\(^1\)Our derivation can easily be extended to an intersection of more than two streets and streets with more than two lanes.

\(^2\)This is an extension of the work we reported in [2] where we only considered two phases: green and red.
Let $l_i(t)$ be the queue length (i.e., the number of cars waiting) in lane $L_i$ at time instant $t$. In reality $l_i(t)$ will be an integer valued function and the arrival and departure rates will vary as a function of time. As a consequence, the exact model for the evolution of the queue lengths is not very amenable to mathematical analysis. Therefore, we introduce some assumptions that will result in a much simpler (approximate) model that can be analyzed very easily and for which we can efficiently compute optimal traffic light switching schemes (see Section 3).

We make the following assumptions:

- the queue lengths are continuous variables,
- in each main phase the average arrival and departure rates of the cars are constant\(^3\),
- for each lane the average departure rate during a green phase is greater than or equal to the average departure rate during the subsequent amber phase.

The first two assumptions deserve a few remarks:

- Designing optimal traffic light switching schemes is only useful if the arrival and departure rates of vehicles at the intersection are high. In that case, approximating the queue lengths by continuous variables only introduces small errors. Furthermore, there is also some uncertainty and variation in time of the arrival and departure rates, which makes that in general the exact optimal traffic light switching scheme is utopian. Moreover, in practice we are more interested in quickly obtaining a good approximation of the optimal traffic light switching scheme than in spending a large amount of time to obtain the exact optimal traffic light switching scheme.

- If we keep in mind that one of the main purposes of the model that we shall derive, is the design of optimal traffic light switching schemes, then assuming that the average arrival and departure rates are constant in each phase is not a serious restriction since we can approximate time-varying arrival and departure rates by piecewise constant functions\(^4\). Moreover, we can also use a moving horizon strategy: we compute the optimal traffic light switching scheme for, say, 10 cycles, based on a prediction of the average arrival and departure rates (using historical data and data measured during the previous cycles) and apply this scheme during the first of the 10 cycles, meanwhile we update our estimates of the arrival and departure rates and compute a new optimal scheme for the next 10 cycles, and so on.

Let $\bar{\lambda}_i^{(k)}$ be the average arrival rate of vehicles in lane $L_i$ in time interval $(t_k, t_{k+1})$. Let $\bar{\mu}_i^{(k)}$ (respectively $\bar{\kappa}_i^{(k)}$) be the average departure rate in lane $L_i$ in time interval $(t_k, t_{k+1})$ when the traffic light is green (respectively amber) and the queue length is larger than 0 (i.e., when there are cars waiting or arriving at lane $L_i$).

Let us now write down the equations that describe the relation between the queue lengths at the main switching time instants. Consider lane $L_1$. When the traffic light $T_1$ is red, there are arrivals at lane $L_1$ and no departures. Hence, for $t \in (t_2k, t_2k+1)$ and

$$l_1(t_{2k+1}) = l_1(t_2k) + \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} \delta_{2k}.$$ 

In the time interval $(t_{2k}+1, t_{2k}+2)$ the traffic light $T_1$ is green and there are arrivals and departures at lane $L_1$. Since the net queue growth rate is $\bar{\lambda}_1^{(2k)} - \bar{\mu}_1^{(2k)}$, and since the queue length cannot be negative, we have

$$\frac{dl_1(t)}{dt} = \begin{cases} \bar{\lambda}_1^{(2k)} - \bar{\mu}_1^{(2k)} & \text{if } l_1(t) > 0 \\ 0 & \text{if } l_1(t) = 0 \end{cases}$$

for $t \in (t_{2k+1}, t_{2k+2} - \delta_k)$. We can write down a similar expression for the amber phase $(t_{2k+2} - \delta_k, t_{2k+2})$. So

$$l_1(t_{2k+2} - \delta_k) = \max \left( l_1(t_{2k+1}) + \left( \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} - \bar{\kappa}_1^{(2k)} \right) (\delta_{2k+1} - \delta_k), 0 \right)$$

$$l_1(t_{2k+2}) = \max \left( l_1(t_{2k+2} - \delta_k) + \left( \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} - \bar{\kappa}_1^{(2k)} \right) 0 \right)$$

$$= \max \left( l_1(t_{2k+1}) + \left( \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} - \bar{\kappa}_1^{(2k)} \right) 0 \right)$$

$$\delta_{2k+1} + \left( \bar{\kappa}_1^{(2k)} - \bar{\mu}_1^{(2k)} \right) \delta_k,$$

$$= \left( \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} - \bar{\kappa}_1^{(2k)} \right) \delta_k.$$ 

Note that we also have

$$l_1(t_{2k+1}) = \max \left( l_1(t_{2k}) + \frac{\bar{\lambda}_1^{(2k)}}{\bar{\mu}_1^{(2k)}} \delta_{2k}, 0 \right)$$

since $l_1(t) \geq 0$ for all $t$. We can write down similar equations for $l_2(t_k)$, $l_3(t_k)$ and $l_4(t_k)$. So if we define

$$x_k = \left[ \begin{array}{c} l_1(t_k) \\ l_2(t_k) \\ l_3(t_k) \\ l_4(t_k) \end{array} \right]^T,$$

we obtain

$$x_{2k+1} = \max \left( x_{2k} + b_1^{(2k)} \delta_{2k} + b_2^{(2k)} b_2^{(2k)} \right)$$

$$x_{2k+2} = \max \left( x_{2k+1} + b_1^{(2k+1)} \delta_{2k+1} + b_2^{(2k+1)} + b_2^{(2k+1)} \right)$$

\(^3\)This is an extension of the work reported in [3] where we required the average arrival and departure rates to be constant whereas in this paper these rates may vary from phase to phase.

\(^4\)In order to determine the average rates for each green-amber or red phase, we could first assume that all main phases have equal length. Then we compute the optimal scheme and use the result to get better estimates of the average rates for the main phases, which can then be used as the input for another optimization run. If necessary we could repeat this process a few times.
for \( k = 0, 1, 2, \ldots \) and for appropriately defined vectors \( b_1(k), b_2(k) \)
and \( b_3(k) \).

3 Optimal traffic light control

3.1 Problem statement

From now on we assume that the average arrival and departure
rates in each main phase are known. For a given integer
\( N \) we want to compute an optimal sequence \( t_0, t_1, \ldots, t_N \)
of switching time instants that minimizes a criterion such as:

- (weighted) average queue length over all queues:
  \[ J_1 = \sum_{i=1}^{4} \frac{w_i}{t_N - t_0} \int_{t_0}^{t_N} l_i(t) \, dt, \quad (3) \]

- (weighted) average queue length over the worst queue:
  \[ J_2 = \max_{i} \left( \frac{w_i}{t_N - t_0} \int_{t_0}^{t_N} l_i(t) \, dt \right), \quad (4) \]

- (weighted) worst case queue length:
  \[ J_3 = \max_{i, t} \left( w_i l_i(t) \right), \quad (5) \]

- (weighted) average waiting time over all queues:
  \[ J_4 = \sum_{i=1}^{4} \frac{w_i}{t_N - t_0} \left( \sum_{k=0}^{N-1} \int_{t_k}^{t_{k+1}} \frac{l_i(t)}{\lambda_i^{(2)}} \, dt \right), \quad (6) \]

- (weighted) average waiting time over the worst queue:
  \[ J_5 = \max_{i} \left( \frac{w_i}{t_N - t_0} \sum_{k=0}^{N-1} \int_{t_k}^{t_{k+1}} \frac{l_i(t)}{\lambda_i^{(2)}} \, dt \right), \quad (7) \]

where \( w_i > 0 \) for all \( i \).

We can impose some extra conditions such as minimum and
maximum durations for the green times, maximum queue
lengths, and so on. This leads to the following problem:

\[ \text{minimize } J \quad (8) \]

subject to

where \( \delta_{\text{min},g,i}^{(k)} \) and \( \delta_{\text{max},g,i}^{(k)} \) are the minimum and maximum
green time in lane \( L_i \) in \( (t_k, t_{k+1}) \), \( (x_{\text{max}}^{(k)})_i \) is the maximum
queue length in \( L_i \) in \( (t_k, t_{k+1}) \), \( \alpha_N = \{0, 1, \ldots, \lfloor \frac{N}{2} \rfloor \} \),
\( \beta_N = \{0, 1, \ldots, \lfloor \frac{N}{2} \rfloor \} \) and \( \gamma_N = \{1, 2, \ldots, N \} \).

Now we discuss some methods to solve problem (8) – (13). Consider (12) for an arbitrary index \( k \). It is easy to verify [3]
that this equation is equivalent to:

\[ x_{2k+1} - x_{2k} - b_1(2k) \delta_{2k} - b_2(2k) \geq 0 \quad (14) \]
\[ x_{2k+1} - b_3(2k) \geq 0 \quad (15) \]
\[ \sum_{i=1}^{4} (x_{2k+1} - x_{2k} - b_1(2k) \delta_{2k} - b_2(2k)) = 0 \quad (16) \]

We can repeat this reasoning for (13) and for each \( k \). So if we define

\[ x^* = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_N \end{bmatrix} \quad \text{and} \quad \delta^* = \begin{bmatrix} \delta_{0} \\ \delta_{1} \\ \vdots \\ \delta_{N-1} \end{bmatrix}, \]

we finally get a problem of the following form:

\[ \text{minimize } J \quad (17) \]

subject to

\[ Ax^* + B \delta^* + c \geq 0 \quad (18) \]
\[ x^* + d \geq 0 \quad (19) \]
\[ Ex^* + F \delta^* + g \geq 0 \quad (20) \]
\[ (Ax^* + B \delta^* + c)^T (x^* + d) = 0 \quad (21) \]

The system (18) – (21) is a special case of an Extended Lin-
ear Complementarity Problem (ELCP) [1]. In [1] we have
developed an algorithm to compute a parametric description
of the complete solution set of an ELCP. Once this parameti-
descripion is obtained, we can compute for which combi-
nation of the parameters the objective function \( J \) reaches
a global minimum. However, since the general ELCP is
an NP-hard problem [1], the ELCP based approach is not
feasible if the number of switching cycles \( N \) is large. If \( N \)
is large, we could consider a small number \( N_s \) of switch-
ing cycles, compute the optimal switching strategy with the
method given above, implement the first step(s) of this stra-
tegy, and recompute the optimal switching strategy for the
next \( N_s \) switching cycles. This approach is called the multi-
ELCP approach. Note that although this is feasible in prac-
tice, it will only give a suboptimal solution.

We can also consider problem (8) – (13) as a constrained op-
timization problem in \( \delta^* \) where the constraints (11) – (13)
are considered as nonlinear constraints; alternatively these
constraints can also be taken into account by adding an extra penalty term for values of $x_k$ that exceed $x_{\text{max}}$ to the objective function. The major disadvantage of these two approaches is that in general the minimization routine will only return a local minimum. Our computational experiments have shown that several initial starting points are necessary to obtain the global minimum.

### 3.2 The relaxed problem and suboptimal solutions

Now we make another approximation that will result in suboptimal traffic light switching schemes that can be computed very efficiently and that approximate the exact optimum very well.

For given $x_0$ and $t_0$, we define the function $\tilde{l}_i(\cdot, x^*, \delta^*)$ as the piecewise-linear function that interpolates in the points $(t_k, l_i(t_k))$ for $k = 0, 1, \ldots, N$. The approximate objective functions $\tilde{J}_i$ are defined as in (3)–(7) but with $l_i$ replaced by $\tilde{l}_i$. It is easy to verify that the values of $J_i$ and $\tilde{J}_i$ coincide. Now let $l \in \{1, 2, 4, 5\}$. The value of $J_l$ and $\tilde{J}_l$ is determined by the surface under the functions $l_i$ and $\tilde{l}_i$ respectively. If the duration of the amber phase is zero and if the queue lengths never become zero, then the functions $l_i$ and $\tilde{l}_i$ and the values of $J_l$ and $\tilde{J}_l$ coincide (cf. Figure 2). In practice, the length of the amber phase will be small compared to the length of the green or red phases. Furthermore, an optimal traffic light switching scheme implies the absence of long periods in which no cars wait in one lane while in the other lanes the queue lengths increase. So if we have an optimal traffic light switching scheme, then the periods during which the queue length in some lane is equal to 0 are in general short. As a consequence, for traffic light switching schemes in the neighborhood of the optimal scheme $J_l$ will be a good approximation of $\tilde{J}_l$.

Let $P$ be the problem (8)–(13). We define the “relaxed” problem $\tilde{P}$ corresponding to the original problem $P$ as:

\[
\text{minimize } \tilde{J}_i
\]

subject to

\[
\delta^{(2k)}_{\text{min},g,1} \leq \delta_{2k} - \delta_{i} \leq \delta^{(2k)}_{\text{max},g,1} \quad \text{for } k \in \alpha_N \tag{24}
\]

\[
x_k \leq x_{\text{max}} \quad \text{for } k \in \gamma_N \tag{25}
\]

\[
x_{2k+1} \geq x_{2k} + b_{1}^{(2k)} \delta_{2k} + b_{2}^{(2k)} \quad \text{for } k \in \alpha_N \tag{26}
\]

\[
x_{2k+1} \geq b_{3}^{(2k)} \quad \text{for } k \in \alpha_N \tag{27}
\]

\[
x_{2k+2} \geq x_{2k+1} + b_{1}^{(2k+1)} \delta_{2k+1} + b_{2}^{(2k+1)} \quad \text{for } k \in \beta_N \tag{28}
\]

\[
x_{2k+2} \geq b_{3}^{(2k+1)} \quad \text{for } k \in \beta_N \tag{29}
\]

Note that compared to the original problem we have replaced (12)–(13) by relaxed equations of the form (14)–(15) without taking (16) into account. In general it is easier to solve $\tilde{P}$ since the set of feasible solutions of $\tilde{P}$ is convex, whereas the set of feasible solutions of $P$ corresponds to an ELCP and is thus in general not convex [3].

**Proposition 3.1** If $J$ is a strictly monotonic function of $x^*$ — i.e., if for any $\delta^*$ with positive components and for all $\tilde{x}, \tilde{x}'$ with $0 \leq \tilde{x} \leq \tilde{x}'$ and with $\tilde{x}_j^* < \tilde{x}'_j$ for at least one index $j$, we have $J(\tilde{x}, \delta^*) < J(\tilde{x}', \delta^*)$ — then any solution of the relaxed problem $\tilde{P}$ is also a solution of the original problem $P$.

**Proof:** The proof is similar to that of Proposition 3.2 of [3]. The main difference is that in [3] we assumed that the average arrival and departure rates were constant during the whole period $(t_0, t_N)$, whereas in this paper we allow them to vary from one main phase to another.

Using a reasoning similar to the one of [3] it can be shown that $\tilde{J}_l$ and $\tilde{J}_l$ are strictly monotonic functions of $x^*$, i.e., they satisfy the conditions of Proposition 3.1. Furthermore, if all the $\tilde{\delta}_k$’s are equal then $\tilde{J}_l$ and $\tilde{J}_l$ are linear, strictly monotonic functions of $x^*$, which implies that problem (8)–(13) then reduces to a linear programming problem, which can be solved efficiently using a simplex or interior point method. In [3] we also discuss some extensions of the basic model such as: an amber duration that is a variable or that depends on $k$; streets consisting of more than two lanes; different average departure rates for vehicles that turn left, right or go straight ahead; and intersections of networks.
Table 2: The values of the objective function $J_4$ (up to 3 decimal places) and the CPU time (up to 2 decimal places) needed to compute the (sub)optimal switching interval vectors of the example of Section 4.

4 Example

The following example illustrates that using the approximations introduced in the Section 3.2 for the objective functions $J_4$ leads to good suboptimal solutions that can be computed very efficiently. All times will be expressed in seconds and all rates in vehicles per second.

Consider the intersection of Figure 1 with the following data: $\bar{\lambda}_1(k) = 0.22$, $\bar{\lambda}_2(k) = 0.13$, $\bar{\lambda}_3(k) = 0.19$, $\bar{\lambda}_4(k) = 0.12$, $\bar{\mu}_1(k) = \bar{\mu}_3(k) = 0.5$, $\bar{\mu}_2(k) = \bar{\mu}_4(k) = 0.4$, $\bar{k}_1(k) = \bar{k}_3(k) = 0.05$, $\bar{k}_2(k) = \bar{k}_4(k) = 0.03$, $x_0 = [22 18 15 14]^T$, $\delta_0 = 3$, $\delta_{min,g,1} = \delta_{max,g,1} = 6$, $\delta_{max,g,2} = 60$, $x_{max} = [25 15 15 15]^T$.

Let $\mathbf{w} = [2 1 2 1]^T$. We want to compute a traffic light switching sequence $t_0, t_1, \ldots, t_7$ that minimizes the weighted average waiting time $J_4$. We have computed an optimal solution $\delta^*_{ELCP}$ obtained using the ELCP method, a solution $\delta^*_{con}$ using constrained optimization with nonlinear constraints, a solution $\delta^*_{pen}$ using constrained optimization with a penalty function, a multi-ELCP solution $\delta^*_{mul}$ with $N_c = 3$, a solution $\delta^*$ that minimizes the approximate objective function $J_4$ and a linear programming solution $\delta^*_{lin}$. In Table 2 we have listed the value of the objective function $J_4$ for the various switching interval vectors and the CPU time needed to compute the switching interval vectors on a SUN Ultra 10 300 MHz workstation with the optimization routines called from MATLAB and implemented in C or Fortran. The CPU time values listed in the table are average values over 10 experiments.

If we look at Table 2 then we see that if we take the trade-off between optimality and efficiency into account, then the $\delta^*$ solution is clearly the most interesting.

5 Conclusions

We have derived a model that describes the evolution of the queue lengths at a traffic light controlled intersection of two streets. We have shown how an optimal traffic light switching scheme for the given system can be determined. In general this leads to a minimization problem over the solution set of an Extended Linear Complementarity Problem. For objective functions that depend strictly monotonously on the queue lengths at the traffic light switching time instants, the optimal traffic light switching scheme can be computed very efficiently. We have derived approximate objective functions for which this property holds. Moreover, if the objective function is linear, the problem reduces to a linear programming problem.

Topics for further research include: extension of our approach to models with integer queue lengths, extension to centralized traffic light control for networks of intersections, and development of other efficient algorithms to compute optimal traffic light switching schemes.
